# QED RISCMark™ RM7000™

64-Bit Superscalar Microprocessor
Advanced Information

FEATURES:

- RM5270 and RM5271 pin compatible
- Dual Issue symmetric superscalar microprocessor with instruction prefetch optimized for system level price/performance
  — 200, 225, 250, 263 MHz operating frequency
  — >450 Dhrystone 2.1 MIPS @ 263 MHz
  — 11-13 SPECint95, 13-15 SPECfp95 @ 263 MHz
  — MIPS IV Superset Instruction Set Architecture
- High-performance interface (RM52xx compatible)
  — 1000 MB per second peak throughput
  — 125 MHz max. freq., multiplexed address/data
  — Supports two outstanding reads with out-of-order return
  — Supports $\frac{1}{2}$ clock divisors (2, 2.5, 3, 3.5, 4, 4.5, 5, 6, 7, 8, 9)
  — IEEE 1149.1 JTAG (TAP) boundary scan
- Integrated primary and secondary caches - all are 4-way set associative with 32 byte line size
  — 16KB instruction
  — 16KB data: non-blocking and write-back or write-through
  — 256KB on-chip secondary: unified, non-blocking, block write-back
  — Per line cache locking in primaries and secondary
- Integrated tertiary cache controller (RM527x compatible)
  — Supports 512K, 1M, 2M, 4M, or 8 MByte block write-through
- MIPS IV instruction set
  — Data PREFETCH instruction allows the processor to overlap cache miss latency and instruction execution
  — Floating point combined multiply-add instruction increases performance in signal processing and graphics applications
  — Conditional moves reduce branch frequency
  — Index address modes (register + register)

- Integrated memory management unit (RM52xx compatible)
  — Fully associative joint TLB (shared by I and D translations)
  — 48 dual entries map 96 pages
  — 4 entry DTLB and 4 entry ITLB
  — Variable page size (4KB to 16MB in 4x increments)
- Embedded application enhancements
  — Specialized DSP integer Multiply-Accumulate instruction, (MAD/MADU) and three-operand multiply instruction (MUL/MULU)
  — I&D Test/Break-point (Watch) registers for emulation & debug
  — Performance counter for system and software tuning & debug
  — Fourteen fully prioritized vectored interrupts - 10 external, 2 internal, 2 software
  — Bypass secondary/tertiary cache option
  — Fast Hit-Writeback-Invalidate and Hit-Invalidate cache operations for efficient cache management
- High-performance floating-point unit - 600 M FLOPS maximum
  — Single cycle repeat rate for common single-precision operations and some double-precision operations
  — Single cycle repeat rate for single-precision combined multiply-add operations
  — Two cycle repeat rate for double-precision multiply and double-precision combined multiply-add operations
- Fully static CMOS design with dynamic power down logic
  — Standby reduced power mode with WAIT instruction
  — 3.3 watts typical @ 2.5V Int., 3.3V I/O, 200MHz
- 304 pin SBGA package, 31x31mm

BLOCK DIAGRAM:
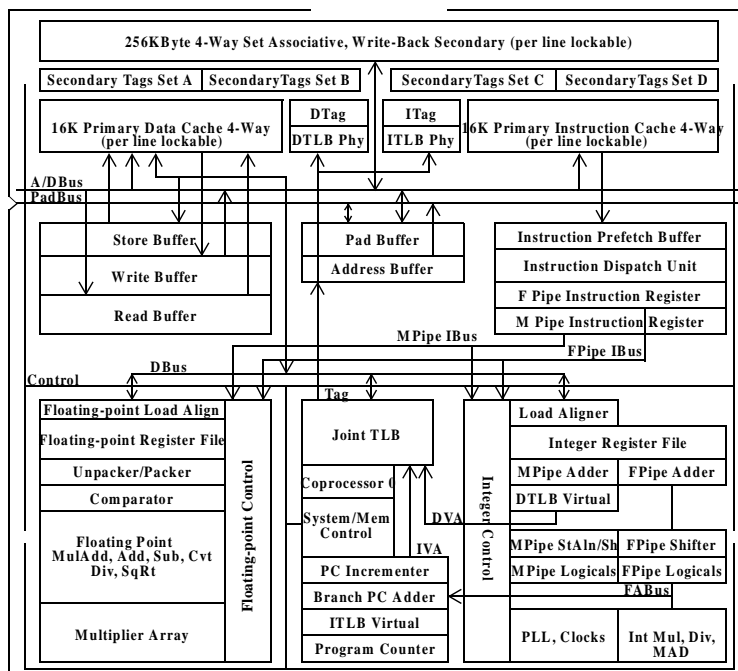

DESCRIPTION:

The QED RM7000 is a highly integrated symmetric super-scalar microprocessor capable of issuing two instructions each processor cycle. It has two high-performance 64-bit integer units as well as a high-throughput, fully pipelined 64-bit floating point unit. To keep its multiple execution units running efficiently, the RM7000 integrates not only 16KB 4-way set associative instruction and data caches but backs them up with an integrated 256KB 4-way set associative secondary as well. For maximum efficiency, the data and secondary caches are write-back and non-blocking. An optional external tertiary cache provides high-performance capability even in applications having very large data sets. A RM52xx family compatible, operating system friendly

memory management unit with a 48-entry fully associative TLB and a high-performance 64-bit system interface supporting multiple outstanding reads with out-of-order return and hardware prioritized and vectored interrupts round out the main features of the processor.

The RM7000 is ideally suited for high-end embedded control applications such as internetworking, high-performance image manipulation, high-speed printing, and 3-D visualization. The RM7000 is also applicable to the low end workstation market where its balanced integer and floating-point performance and direct support for a large tertiary cache (up to 8MB) provide outstanding price/performance.

HARDWARE OVERVIEW

The RM7000 offers a high-level of integration targeted at high-performance embedded applications. The key elements of the RM7000 are briefly described below.

CPU Registers

Like all MIPS ISA processors, the RM7000 CPU has a simple, clean user visible state consisting of 32 general purpose registers, or GPR's, two special purpose registers for integer multiplication and division, and a program counter; there are no condition code bits. Figure 1 on page 2 shows the user visible state.

Superscalar Dispatch

The RM7000 has an efficient symmetric superscalar dispatch unit which allows it to issue up to two instructions per cycle. For purposes of instruction issue, the RM7000 defines four classes of instructions: integer, load/store, branches, and floating-point. There are two logical pipelines, the *function*, or F, pipeline and the *memory*, or M, pipeline. Note however that the M pipe can execute integer as well as memory type instructions. Table 1 illustrates the instruction classes which can issue together.

Table 1: Instruction Issue Rules

F Pipe	M Pipe
one of:	one of:
integer, branch, floating-point, integer mul, div	integer, load/store

Figure 2 on page 3 is a simplification of the pipeline section of the cover block diagram and illustrates the basics of the instruction issue mechanism. The figure illustrates that one F pipe instruction and one M pipe instruction can be issued concurrently but that two M pipe or two F pipe instructions cannot be issued.

Table 2, on page 2 specifies more completely the instructions within each class.

Figure 2 Instruction Issue Paradigm

The symmetric superscalar capability of the RM7000, in combination with its low latency integer execution units and high-throughput fully pipelined floating-point execution unit, provides unparalleled price/performance in computational intensive embedded applications.

Pipeline

The logical length of both the F and M pipelines is five stages with state committing in the register write, or W, pipe stage. The physical length of the floating-point execution pipeline is actually seven stages but this is completely transparent to the user.

Figure 3 shows instruction execution within the RM7000 when instructions are issuing simultaneously down both pipelines. As illustrated in the figure, up to ten instructions can be executing simultaneously. This figure presents a somewhat simplistic view of the processors operation however since the out-of-order completion of loads, stores, and long latency floating-point operations can result in there being even more instructions in process than what is shown. On the other hand, instruction dependencies, resource conflicts, and branches will result in some of the instruction slots being occupied by NOPs.

Integer Unit

Like the RM52xx family, the RM7000 implements the MIPS IV Instruction Set Architecture, and is therefore fully upward compatible with applications that run on processors such as the R4600 and R4700 that implement the earlier generation MIPSIII Instruction Set Architecture. Additionally, the RM7000 includes two implementation specific instructions not found in the baseline MIPS IV ISA, but that are useful in the embedded market place. Described in detail in a later section, these instructions are integer multiply-accumulate and three-operand integer multiply.

The RM7000 integer unit includes thirty-two general purpose 64-bit registers, the *HI/LO* result registers for the two-operand integer multiply/divide operations, and the program counter, or PC. There are two separate execution units, one of which can execute function, or F, type instructions and one which can execute memory, or M, type instructions. See above for a description of the instruction

Figure 3 Pipeline

types and the issue rules. As a special case, integer multiply/divide instructions as well as their corresponding **MFHI** and **MFLO** instructions can only be executed in the F type execution unit. Within each execution unit the operational characteristics are the same as on previous QED designs with single cycle ALU operations (add, sub, logical, shift), one cycle load delay, and an autonomous multiply/divide unit.

Register File

The RM7000 has thirty-two general purpose registers with register location 0 (*r0*) hard wired to a zero value. These registers are used for scalar integer operations and address calculation. In order to service the two integer execution units, the register file has four read ports and two write ports and is fully bypassed both within and between the two execution units to minimize operation latency in the pipeline.

ALU

The RM7000 has two complete integer ALU's each consisting of an integer adder/subtractor, a logic unit, and a shifter. Table 3 below shows the functions performed by the ALU's for each execution unit. Each of these units is optimized to perform all operations in a single processor cycle.

Table 3: ALU Functions

Unit	F Pipe	M Pipe
Adder	add, sub	add, sub, data address add
Logic	logic, moves, zero shifts (nop)	logic, moves, zero shifts (nop)
Shifter	non zero shift	non zero shift, store align

Integer Multiply/Divide

The RM7000 has a single dedicated integer multiply/divide unit optimized for high-speed multiply and multiply-accumulate operations. The multiply/divide unit resides in the F type execution unit. Table 4 shows the performance of the multiply/divide unit on each operation.

Table 4: Integer Multiply/Divide Operations

Opcode	Operand Size	Latency	Repeat Rate	Stall Cycles
MULT/U, MAD/U	16 bit	4	3	0
	32 bit	5	4	0
MUL	16 bit	4	3	2
	32 bit	5	4	3
DMULT, DMULTU	any	9	8	0
DIV, DIVD	any	36	36	0
DDIV, DDIVU	any	68	68	0

The baseline MIPS IV ISA specifies that the results of a multiply or divide operation be placed in the *Hi* and *Lo* registers. These values can then be transferred to the general purpose register file using the Move-from-Hi and Move-from-Lo (**MFHI**/**MFLO**) instructions.

In addition to the baseline MIPS IV integer multiply instructions, the RM7000 also implements the multiply instruction, **MUL**. This instruction specifies that the multiply result go directly to the integer register file rather than the *Lo* register. The portion of the multiply that would have normally gone into the *Hi* register is discarded. For applications where it is known that the upper half of the multiply result is not required, using the **MUL** instruction eliminates the necessity of executing an explicit **MFLO** instruction.

Also included in the RM7000 is the multiply-add instruction, **MAD**. This instruction multiplies two operands and adds the resulting product to the current contents of the *Hi* and *Lo* registers. The multiply-accumulate operation is the core primitive of almost all signal processing algorithms allowing the RM7000 to eliminate the need for a separate DSP engine in many embedded applications.

By pipelining the multiply-accumulate function and dynamically determining the size of the input operands, the RM7000 is able to maximize throughput while still using an area efficient implementation.

Floating-Point Coprocessor

The RM7000 incorporates a high-performance fully pipelined floating-point coprocessor which includes a floating-point register file and autonomous execution units for multiply/add/convert and divide/square root. The floating-point coprocessor is a tightly coupled co-execution unit, decoding and executing instructions in parallel with, and in the case of floating-point loads and stores, in cooperation with the M pipe of the integer unit. As described earlier, the superscalar capabilities of the RM7000 allow floating-point computation instructions to issue concurrently with integer instructions.

Floating-Point Unit

The RM7000 floating-point execution unit supports single and double precision arithmetic, as specified in the IEEE Standard 754. The execution unit is broken into a separate divide/square root unit and a pipelined multiply/add unit. Overlap of divide/square root and multiply/add is supported.

The RM7000 maintains fully precise floating-point exceptions while allowing both overlapped and pipelined operations. Precise exceptions are extremely important in object-oriented programming environments and highly desirable for debugging in any environment.

The floating-point unit's operation set includes floating-point add, subtract, multiply, multiply-add, divide, square root, reciprocal, reciprocal square root, conditional moves, con-

version between fixed-point and floating-point format, conversion between floating-point formats, and floating-point compare.

Table 5 gives the latencies of the floating-point instructions in internal processor cycles.

Floating-Point General Register File

The floating-point general register file, FGR, is made up of thirty-two 64-bit registers. With the floating-point load and store double instructions, **LDC1** and **SDC1**, the floating-point unit can take advantage of the 64-bit wide data cache and issue a floating-point coprocessor load or store double-word instruction in every cycle.

The floating-point control register file contains two registers; one for determining configuration and revision information for the coprocessor and one for control and status information. These registers are primarily used for diagnostic software, exception handling, state saving and restoring, and control of rounding modes.

To support superscalar operation, the FGR has four read ports and two write ports, and is fully bypassed to minimize operation latency in the pipeline. Three of the read ports and one write port are used to support the combined multi-

ply-add instruction while the fourth read and second write port allows a concurrent floating-point load or store and conditional moves.

System Control Coprocessor (CP0)

The system control coprocessor, coprocessor 0 or CP0, in the MIPS architecture is responsible for the virtual memory sub-system, the exception control system, and the diagnostics capability of the processor. In the MIPS architecture, the system control coprocessor (and thus the kernel software) is implementation dependent. For memory management, the RM7000 CP0 is logically identical to that of the RM52xx family and R5000. For interrupt exceptions and diagnostics, the RM7000 is a superset of the RM52xx family and R5000 implementing additional features described later in the sections on Interrupts, the Test/Breakpoint facility, and the Performance Counter facility.

The memory management unit controls the virtual memory system page mapping. It consists of an instruction address translation buffer, or ITLB, a data address translation buffer, or DTLB, a Joint TLB, or JTLB, and coprocessor registers used by the virtual memory mapping sub-system.

System Control Coprocessor Registers

The RM7000 incorporates all system control coprocessor (CP0) registers internally. These registers provide the path through which the virtual memory system's page mapping is examined and modified, exceptions are handled, and operating modes are controlled (kernel vs. user mode, interrupts enabled or disabled, cache features). In addition, the RM7000 includes registers to implement a real-time cycle counting facility, to aid in cache and system diagnostics, and to assist in data error detection.

To support the non-blocking caches and enhanced interrupt handling capabilities of the RM7000, both the data and control register spaces of CP0 are supported by the RM7000. In the data register space, that is the space accessed using the **MFC0** and **MTC0** instructions, the RM7000 supports the same registers as found in the RM52xx, R4000 and R5000 families. In the control space, that is the space accessed by the previously unused **CTC0** and **CFC0** instructions, the RM7000 supports five new registers. The first three of these new 32-bit registers support the enhanced interrupt handling capabilities and are the *Interrupt Control, Interrupt Priority Level Lo (IPLLO), and Interrupt Priority Level Hi (IPLHI)* registers. These registers are described further in the section on interrupt handling. The other two registers, *Imprecise Error 1* and *Imprecise Error 2*, have been added to help diagnose bus errors which occur on non-blocking memory references.

Figure 4 shows the CP0 registers.

Figure 4 CP0 Registers

- user mode
- supervisor mode
- kernel mode

This mechanism is available to system software to provide a secure environment for user processes. Bits in the CP0 *Status* register determine which virtual addressing mode is used. In the user mode, the RM7000 provides a single, uniform virtual address space of 256GB (2GB in 32-bit mode).

When operating in the kernel mode, four distinct virtual address spaces, totalling 1024GB (4GB in 32-bit mode), are simultaneously available and are differentiated by the high-order bits of the virtual address.

The RM7000 processor also supports a supervisor mode in which the virtual address space is 256.5GB (2.5GB in 32-bit mode), divided into three regions based on the high-order bits of the virtual address.

Figure 5 on page 6 shows the address space layout for 32-bit operation.

When the RM7000 is configured for 64-bit addressing, the virtual address space layout is an upward compatible extension of the 32-bit virtual address space layout.

Address	Description
0xFFFFFFFF	Kernel virtual address space (kseg3) Mapped, 0.5GB

0x7FFFFFFF	User virtual address space (kuseg) Mapped, 2.0GB
0x00000000	

Figure 5 Kernel Mode Virtual Addressing (32-bit mode)

Joint TLB

For fast virtual-to-physical address translation, the RM7000 uses a large, fully associative TLB that maps 128 virtual pages to their corresponding physical addresses. As indicated by its name, the joint TLB (JTLB) is used for both instruction and data translations. The JTLB is organized as 48 pairs of even-odd entries, and maps a virtual address and address space identifier into the large, 64GB physical address space.

Two mechanisms are provided to assist in controlling the amount of mapped space, and the replacement characteristics of various memory regions. First, the page size can be configured, on a per-entry basis, to use page sizes in the range of 4KB to 16MB (in 4X multiples). A CP0 register, PageMask, is loaded with the desired page size of a mapping, and that size is stored into the TLB along with the virtual address when a new entry is written. Thus, operating systems can create special purpose maps; for example, a typical frame buffer can be memory mapped using only one TLB entry.

The second mechanism controls the replacement algorithm when a TLB miss occurs. The RM7000 provides a random replacement algorithm to select a TLB entry to be written with a new mapping; however, the processor also provides a mechanism whereby a system specific number of mappings can be locked into the TLB, thereby avoiding random replacement. This mechanism allows the operating system to guarantee that certain pages are always mapped for performance reasons and for deadlock avoidance. This mechanism also facilitates the design of real-time systems by allowing deterministic access to critical software.

The JTLB also contains information that controls the cache coherency protocol for each page. Specifically, each page has attribute bits to determine whether the coherency algorithm is: uncached, write-back, write-through with write-allocate, write-through without write-allocate, write-back with secondary and tertiary bypass. Note that both of the write-through protocols bypass both the secondary and the tertiary caches since neither of these caches support writes of less than a complete cache line.

These protocols are used for both code and data on the RM7000 with data using write-back or write-through depending on the application. The write-through modes support the same efficient frame buffer handling as the RM52xx family, R4700 and R5000.

Instruction TLB

The RM7000 uses a 4-entry instruction TLB (ITLB) to minimize contention for the JTLB, to eliminate the critical path of translating through a large associative array, and to save power. Each ITLB entry maps a 4KB page. The ITLB improves performance by allowing instruction address translation to occur in parallel with data address translation. When a miss occurs on an instruction address translation by the ITLB, the least-recently used ITLB entry is filled from the JTLB. The operation of the ITLB is completely transparent to the user.

Data TLB

The RM7000 uses a 4-entry data TLB (DTLB) for the same reasons cited above for the ITLB. Each DTLB entry maps a 4KB page. The DTLB improves performance by allowing data address translation to occur in parallel with instruction address translation. When a miss occurs on a data address translation by the DTLB, the DTLB is filled from the JTLB. The DTLB refill is pseudo-LRU: the least recently used entry of the least recently used pair of entries is filled. The operation of the DTLB is completely transparent to the user.

Cache Memory

In order to keep the RM7000's superscalar pipeline full and operating efficiently, the RM7000 has integrated primary instruction and data caches with single cycle access as well as a large unified secondary cache with a three cycle miss penalty from the primaries. Each primary cache has a 64-bit read path, a 128-bit write path, and both caches can be accessed simultaneously. The primary caches provide the integer and floating-point units with an aggregate bandwidth of 4.256 GB per second at an internal clock frequency of 263 MHz. During an instruction or data primary cache refill, the secondary cache can provide a 64-bit datum every cycle following the initial three cycle latency for a peak bandwidth of 2.4 GB per second. For applications requiring even higher performance, the RM7000 also has a direct interface to a large external tertiary cache.

Instruction Cache

The RM7000 has an integrated 16KB, four-way set associative instruction cache and, even though instruction address translation is done in parallel with the cache access, the combination of 4-way set associativity and 16KB size results in a cache which is physically indexed and physically tagged. Since the effective physical index eliminates the potential for virtual aliases in the cache, it is possible that some operating system code can be simplified vis-a-vis the RM52xx family, R5000 and R4000 class processors.

The data array portion of the instruction cache is 64 bits wide and protected by word parity while the tag array holds a 24-bit physical address, 14 housekeeping bits, a valid bit, and a single bit of parity protection.

By accessing 64 bits per cycle, the instruction cache is able to supply two instructions per cycle to the superscalar dispatch unit. For signal processing, graphics, and other numerical code sequences where a floating-point load or store and a floating-point computation instruction are being issued together in a loop, the entire bandwidth available from the instruction cache will be consumed by instruction issue. For typical integer code mixes, where instruction dependencies and other resource constraints restrict the

achievable parallelism, the extra instruction cache band-width is used to fetch both the taken and non-taken branch paths to minimize the overall penalty for branches.

A 32-byte, eight instruction, line size is used to maximize the communication efficiency between the instruction cache and the secondary cache, tertiary cache, or memory system.

The RM7000 is the first MIPS RISC microprocessor to support cache locking on a per line basis. The contents of each line of the cache can be *locked* by setting a bit in the Tag. Locking the line prevents its contents from being overwritten by a subsequent cache miss. Refill will occur only into unlocked cache lines. This mechanism allows the programmer to lock critical code into the cache thereby guaranteeing deterministic behavior for the locked code sequence.

Data Cache

The RM7000 has an integrated 16KB, four-way set associative data cache, and even though data address translation is done in parallel with the cache access, the combination of 4-way set associativity and 16KB size results in a cache which is physically indexed and physically tagged. Since the effective physical index eliminates the potential for virtual aliases in the cache, it is possible that some operating system code can be simplified vis-a-vis the RM52xx family, R5000 and R4000 class processors.

The data cache is non-blocking; that is, a miss in the data cache will not necessarily stall the processor pipeline. As long as no instruction is encountered which is dependent on the data reference which caused the miss, the pipeline will continue to advance. Once there are two cache misses outstanding, the processor will stall if it encounters another load or store instruction.

A 32-byte, eight instruction, line size is used to maximize the communication efficiency between the data cache and the secondary cache, tertiary cache, or memory system.

The data array portion of the data cache is 64 bits wide and protected by byte parity while the tag array holds a 24-bit physical address, 3 housekeeping bits, a two bit cache state field, and has two bits of parity protection.

The normal write policy is write-back, which means that a store to a cache line does not immediately cause memory to be updated. This increases system performance by reducing bus traffic and eliminating the bottleneck of waiting for each store operation to finish before issuing a subsequent memory operation. Software can, however, select write-through on a per-page basis when appropriate, such as for frame buffers. Cache protocols supported for the data cache are:

1. **Uncached.** Reads to addresses in a memory area identified as uncached will not access the cache. Writes to such addresses will be written directly to main memory without updating the cache.

2. **Write-back.** Loads and instruction fetches will first search the cache, reading the next memory hierarchy level only if the desired data is not cache resident. On data store operations, the cache is first searched to determine if the target address is cache resident. If it is resident, the cache contents will be updated, and the cache line marked for later write-back. If the cache lookup misses, the target line is first brought into the cache and then the write is performed as above.

3. **Write-through with write allocate.** Loads and instruction fetches will first search the cache, reading from memory only if the desired data is not cache resident; write-through data is never cached in the secondary or tertiary caches. On data store operations, the cache is first searched to determine if the target address is cache resident. If it is resident, the primary cache contents will be updated and main memory will also be written leaving the *write-back* bit of the cache line unchanged; no writes will occur into the secondary or tertiary. If the cache lookup misses, the target line is first brought into the cache and then the write is performed as above.

4. **Write-through without write allocate.** Loads and instruction fetches will first search the cache, reading from memory only if the desired data is not cache resident; write-through data is never cached in the secondary or tertiary caches. On data store operations, the cache is first searched to determine if the target address is cache resident. If it is resident, the cache contents will be updated and main memory will also be written leaving the *write-back* bit of the cache line unchanged; no writes will occur into the secondary or tertiary. If the cache lookup misses, then only main memory is written.

Write-back with secondary and tertiary bypass. Loads and instruction fetches will first search the cache, reading from memory only if the desired data is not cache resident; the secondary and tertiary will not be searched. On data store operations, the cache is first searched to determine if the target address is cache resident. If it is resident, the cache contents will be updated, and the cache line marked for later write-back. If the cache lookup misses, the target line is first brought into the cache and then the write is performed as above.

Associated with the Data Cache is the *store buffer*. When the RM7000 executes a **STORE** instruction, this single-entry buffer gets written with the store data while the tag comparison is performed. If the tag matches, then the data is written into the Data Cache in the next cycle that the Data Cache is not accessed (the next non-load cycle). The store buffer allows the RM7000 to execute a store every processor cycle and to perform back-to-back stores without penalty. In the event of a store immediately followed by a load to the same address, a combined merge and cache write will occur such that no penalty is incurred.

Secondary Cache

The RM7000 has an integrated 256KB, four-way set asso-ciative, block write-back secondary cache. The secondary has the same line size as the primaries, 32 bytes, is logi-cally 64-bits wide matching the system interface and pri-mary widths, and is protected with doubleword parity. The secondary tag array holds a 20-bit physical address, 2 housekeeping bits, a three bit cache state field, and two parity bits.

By integrating a secondary cache, the RM7000 is able to dramatically decrease the latency of a primary cache miss without dramatically increasing the number of pins and the amount of power required by the processor. From a technology point of view, integrating a secondary cache maximally leverages CMOS semiconductor technology by using silicon to build the structures that are most amenable to silicon technology; silicon is being used to build very dense, low power memory arrays rather than large power hungry I/O buffers.

Further benefits of an integrated secondary are flexibility in the cache organization and management policies that are not practical with an external cache. Two previously men-tioned examples are the 4-way associativity and write-back cache protocol.

A third management policy for which integration affords flexibility is cache hierarchy management. With multiple lev-els of cache, it is necessary to specify a policy for dealing with cases where two cache lines at level n of the hierarchy would, if possible, be sharing an entry in level n+1 of the hierarchy. The policy followed by the RM7000 is motivated by the desire to get maximum cache utility and results in the RM7000 allowing entries in the primaries which do not necessarily have a corresponding entry in the secondary; the RM7000 does not force the primaries to be a subset of the secondary. For example, if primary cache line A is being filled and a cache line already exists in the secondary for primary cache line B at the location where primary A's line would reside then that secondary entry will be replaced by an entry corresponding to primary cache line A and no action will occur in the primary for cache line B. This opera-tion will create the aforementioned scenario where the pri-mary cache line which initially had a corresponding secondary entry will no longer have such an entry. Such a primary line is called an *orphan*. In general, cache lines at level n+1 of the hierarchy are called *parents* of level n's *chil-dren*.

Another RM7000 cache management optimization occurs for the case of a secondary cache line replacement where the secondary line is dirty and has a corresponding dirty line in the primary. In this case, since it is permissible to leave the dirty line in the primary, it is not necessary to write the secondary line back to main memory. Taking this sce-nario one step further, a final optimization occurs when the aforementioned dirty primary line is replaced by another

line and must be written back, in this case, it will be written directly to memory bypassing the secondary cache.

Secondary Caching Protocols

Unlike the primary data cache, the secondary cache sup-ports only uncached and block write-back. As noted earlier, cache lines managed with either of the write-through proto-cols will not be placed in the secondary cache. A new cach-ing attribute, write-back with secondary and tertiary bypass, allows the secondary, and the tertiary if present, to be bypassed entirely. When this attribute is selected, the secondary and tertiary will not be filled on load misses and will not be written on dirty write-backs from the primary.

Tertiary Cache

Like the RM5270, RM5271 and R5000, the RM7000 has direct support for an external cache. In the case of the RM527x chips this is a secondary cache whereas for the RM7000 this cache becomes a level-3, or tertiary cache. The tertiary cache is direct mapped and block write-through with byte parity protection for data. The RM7000 tertiary operates identical to the secondary of the RM527x and R5000 while supporting additional size increments to 4M and 8M byte caches.

The tertiary interface uses the SysAD bus for data and tags while providing a separate bus, **TcLine**, for addresses, and a handful of tertiary specific control signals (for the com-plete set, see Pin Listing).

A tertiary read looks nearly identical to a standard proces-sor read except that the tag chip enable signal, **TcTCE***, is asserted concurrently with **ValidOut*** and **Release***, initiat-ing a tag probe and indicating to the external controller that a tertiary cache access is being performed. As a result, the external controller monitors the tertiary hit signal, **TcMatch**, and if a hit is indicated the controller will abort the memory read and will refrain from acquiring control of the system interface. Along with **TcTCE***, the processor also asserts the tag data enable signal, **TcTDE***, which causes the tag RAM's to latch the SysAD address internally for use as the replacement tag if a cache miss occurs.

On a tertiary miss, a refill is accomplished with a two signal handshake between the data output enable signal, **TcDOE***, which is deasserted by the controller and the tag and data write enable signal, **TcCWE***, which is asserted by the processor. Figure 6 on page 10 illustrates a hit fol-lowed by a miss in the tertiary cache.

Other capabilities of the tertiary interface include block write, tag invalidate, and tag probe. For details of these transactions as well as detailed timing waveforms for all the tertiary transactions, see the R5000 or RM7000 Bus Inter-face Specifications. The tertiary cache can easily be imple-mented with standard components such as the Motorola MCM69T618.
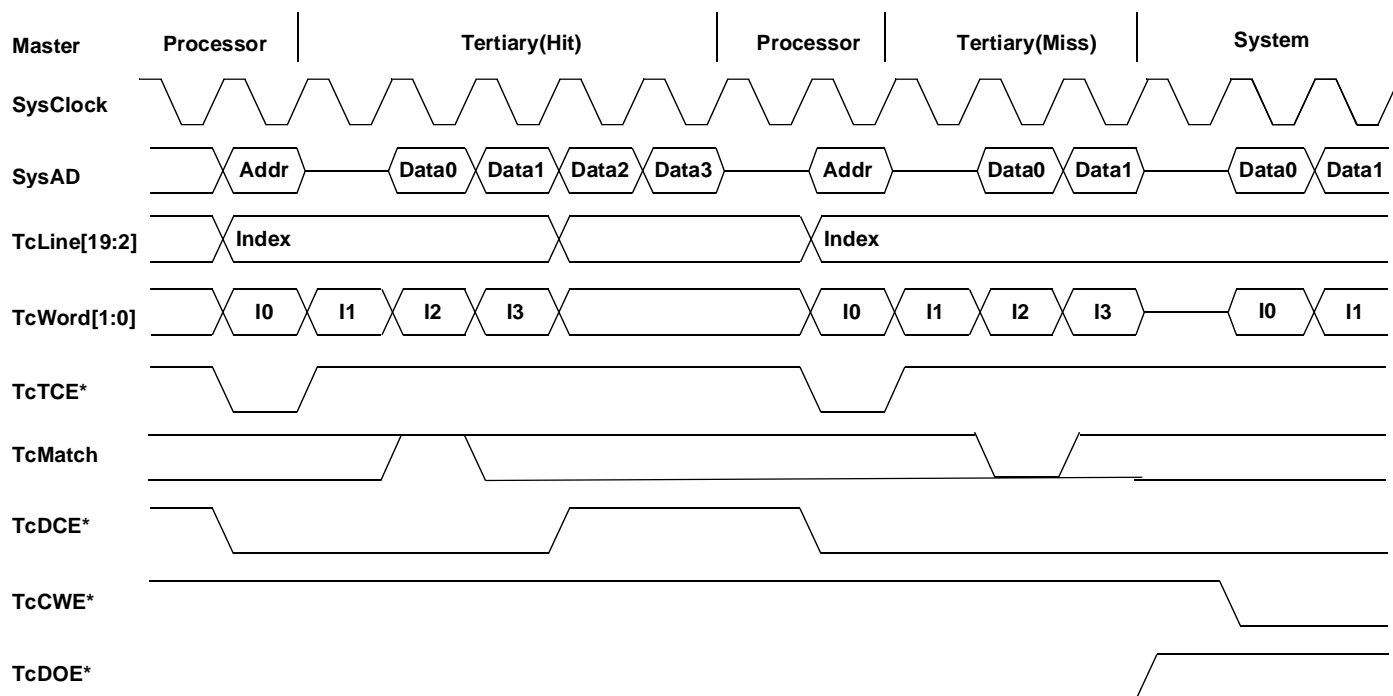

Figure 6 Tertiary Cache Hit and Miss

The RM7000 cache attributes for the instruction, data, internal secondary, and optional external tertiary caches are summarized in Table 6.

Cache Locking

The RM7000 allows critical code or data fragments to be locked into the primary and secondary caches. The user has complete control over what locking is performed with cache line granularity. For instruction and data fragments in the primaries, locking is accomplished by setting either or both of the cache lock enable bits in the CP0 *ECC* register, specifying the set via a field in the CP0 ECC register, and

then executing either a load instruction or a Fill_I cache operation for data or instructions respectively. Only two sets are lockable within each cache: set A and set B. Locking within the secondary works identically to the primaries using a separate secondary lock enable bit and the same set selection field. As with the primaries, only two sets are lockable: sets A and B. Table 7 summarizes the cache locking capabilities.

Cache Management

To improve the performance of critical data movement operations in the embedded environment, the RM7000 sig-

Table 6: Cache Attributes

Attribute	Instruction	Data	Secondary	Tertiary
Size	16KB	16KB	256KB	512K, 2M, or 8M
Associativity	4-way	4-way	4-way	direct mapped
Replacement Algorithm.	cyclic	cyclic	cyclic	direct replacement
Line size	32 byte	32 byte	32 byte	32 byte
Index	$vAddr_{11..0}$	$vAddr_{11..0}$	$pAddr_{15..0}$	$pAddr_{22..0}$
Tag	$pAddr_{35..12}$	$pAddr_{35..12}$	$pAddr_{35..16}$	$pAddr_{35..19}$
Write policy	n.a.	write-back, write-through	block write-back, bypass	block write-through, bypass
read policy	n.a.	non-blocking (2 outstanding)	non-blocking (data only, 2 outstanding)	non-blocking (data only, 2 outstanding)
read order	critical word first	critical word first	critical word first	critical word first
write order	sequential	sequential	sequential	sequential
miss restart following:	complete line	first double (if waiting for data)	n.a.	n.a.
Parity	per word	per byte	per doubleword	per byte

Table 7:   **Cache Locking Control**

Cache	Lock Enable	Set Select	Activate
Primary I	ECC[27]	ECC[28]=0→A ECC[28]=1→B	Fill_I
Primary D	ECC[26]	ECC[28]=0→A ECC[28]=1→B	Load/Store
Secondary	ECC[25]	ECC[28]=0→A ECC[28]=1→B	Fill_I or Load/Store

nificantly improves the speed of operation of certain critical cache management operations vis-a-vis the R5000 and R4000 families. In particular, the speed of the Hit-Write-back-Invalidate and Hit-Invalidate cache operations has been improved in some cases by an order of magnitude over that of the earlier families. Table 8 compares the RM7000 with the R4000 and R5000 processors.

Table 8:   **Penalty Cycles**

Operation	Condition	Penalty	
		RM7000	**R4000/R5000**
Hit-Writeback-Invalidate	Miss	0	7
	Hit-Clean	3	12
	Hit-Dirty	3+n	14+n
Hit-Invalidate	Miss	0	7
	Hit	2	9

For the Hit-Dirty case of Hit-Writeback-Invalidate, if the writeback buffer is full from some previous cache eviction then n is the number of cycles required to empty the write-back buffer. If the buffer is empty then n is zero.

The penalty value is the number of processor cycles beyond the one cycle required to issue the instruction that is required to implement the operation.

Primary Write buffer

Writes to secondary cache or external memory, whether cache miss write-backs or stores to uncached or write-through addresses, use the integrated primary write buffer. The write buffer holds up to four 64-bit address and data pairs. The entire buffer is used for a data cache write-back and allows the processor to proceed in parallel with memory update. For uncached and write-through stores, the write buffer significantly increases performance by decoupling the SysAD bus transfers from the instruction execution stream.

System Interface

The RM7000 provides a high-performance 64-bit system interface which is compatible with the RM52xx family and R5000. Unlike the R4000 and R5000 family processors which provide only an integral multiplication factor between

SysClock and the pipeline clock, the RM7000 also allows half-integral multipliers, thereby providing greater granularity in the designers choice of pipeline and system interface frequencies.

The interface consists of a 64-bit Address/Data bus with 8 check bits and a 9-bit command bus. In addition, there are ten handshake signals and ten interrupt inputs. The interface has a simple timing specification and is capable of transferring data between the processor and memory at a peak rate of 1000MB/sec with a 125MHz SysClock.

Figure 7 on page 12 shows a typical embedded system using the RM7000. This example shows a system with a bank of DRAMs, an optional tertiary cache, and an interface ASIC which provides DRAM control as well as an I/O port.

System Address/Data Bus

The 64-bit System Address Data (SysAD) bus is used to transfer addresses and data between the RM7000 and the rest of the system. It is protected with an 8-bit parity check bus, SysADC.

The system interface is configurable to allow easy interfacing to memory and I/O systems of varying frequencies. The data rate and the bus frequency at which the RM7000 transmits data to the system interface are programmable via boot time mode control bits. Also, the rate at which the processor receives data is fully controlled by the external device. Therefore, either a low cost interface requiring no read or write buffering or a faster, high-performance interface can be designed to communicate with the RM7000. Again, the system designer has the flexibility to make these price/performance trade-offs.

System Command Bus

The RM7000 interface has a 9-bit System Command (SysCmd) bus. The command bus indicates whether the SysAD bus carries an address or data. If the SysAD bus carries an address, then the SysCmd bus also indicates what type of transaction is to take place (for example, a read or write). If the SysAD bus carries data, then the SysCmd bus also gives information about the data (for example, this is the last data word transmitted, or the data contains an error). The SysCmd bus is bidirectional to support both processor requests and external requests to the RM7000. Processor requests are initiated by the RM7000 and responded to by an external device. External requests are issued by an external device and require the RM7000 to respond.

The RM7000 supports one to eight byte and 32-byte block transfers on the SysAD bus. In the case of a sub-double-word transfer, the 3 low-order address bits give the byte address of the transfer, and the SysCmd bus indicates the number of bytes being transferred.
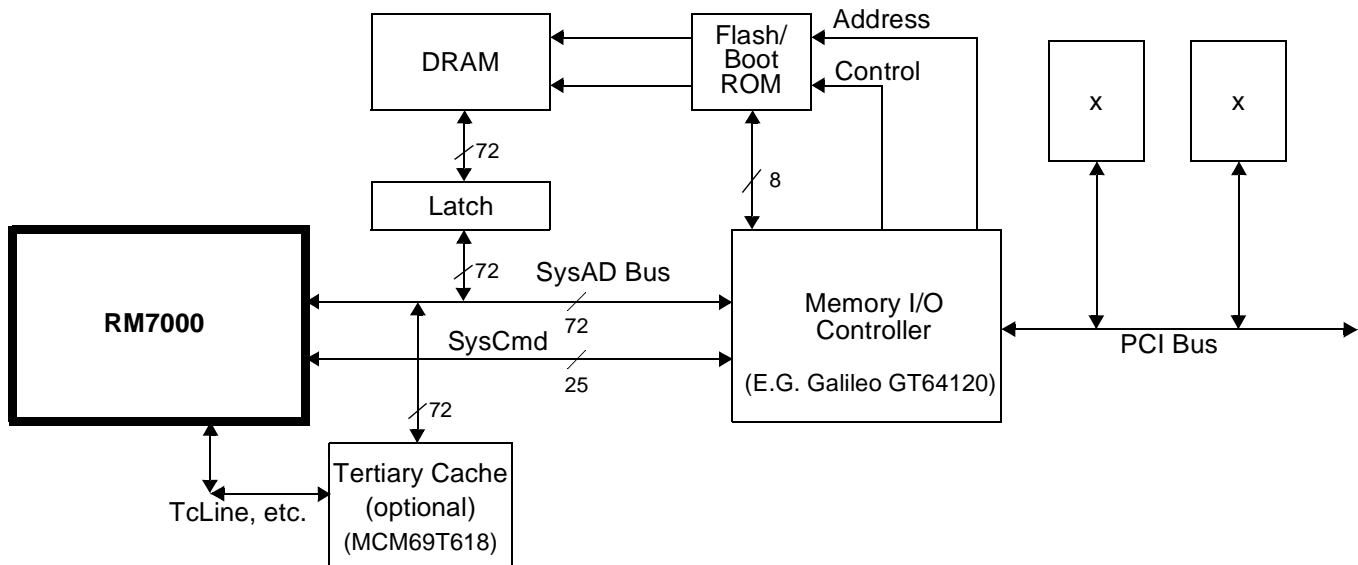

Figure 7 Typical Embedded System Block Diagram

Handshake Signals

There are ten handshake signals on the system interface. Two of these, **RdRdy*** and **WrRdy***, are used by an external device to indicate to the RM7000 whether it can accept a new read or write transaction. The RM7000 samples these signals before deasserting the address on read and write requests.

ExtRqst* and **Release*** are used to transfer control of the SysAD and SysCmd buses from the processor to an external device. When an external device needs to control the interface, it asserts **ExtRqst***. The RM7000 responds by asserting **Release*** to release the system interface to slave state.

PRqst* and **PAck*** are used to transfer control of the SysAD and SysCmd buses from the external agent to the processor. These two pins are new to the interface relative to the RM52x, R4000 and R5000 families and have been added to support multiple outstanding reads and ultimately the non-blocking caches. When the processor needs to reacquire control of the interface, it asserts **PRqst***. The external device responds by asserting **PAck*** to return control of the interface to the processor.

RspSwap* is also a new pin and is used by the external agent to tell the processor when it is returning data out of order; i.e., when there are two outstanding reads, the external agent asserts **RspSwap*** when it is going to return the data for the second read before it returns the data for the first read. **RspSwap*** must be asserted by the external agent two cycles ahead of when it presents data so that the processor has time to switch to the correct address for writes into the tertiary cache.

RdType is the last new pin on the interface. **RdType** indicates whether a read is an instruction read or a data read.

When asserted the reference is an instruction read, when deasserted it is a data read. **RdType** is only valid during valid address cycles.

ValidOut* and **ValidIn*** are used by the RM7000 and the external device respectively to indicate that there is a valid command or data on the SysAD and SysCmd buses. The RM7000 asserts **ValidOut*** when it is driving these buses with a valid command or data, and the external device drives **ValidIn*** when it has control of the buses and is driving a valid command or data.

System Interface Operation

Unlike the R4000 and R5000 processor families, to support the non-blocking caches and data Prefetch instructions, the RM7000 allows two outstanding reads. An external device may respond to read requests in whatever order it chooses by using the response order indicator pin **RspSwap***. No more than two read requests will be submitted to the external device. Other than support for two outstanding reads, operation of the system interface is identical to that of the RM5270, RM5271 and R5000. Support for multiple outstanding reads can be enabled or disabled via a boot-time mode bit.

The RM7000 can issue read and write requests to an external device, while an external device can issue null and write requests to the RM7000.

For processor reads, the RM7000 asserts ValidOut* and simultaneously drives the address and read command on the SysAD and SysCmd buses. If the system interface has **RdRdy*** asserted, then the processor tristates its drivers and releases the system interface to slave state by asserting **Release***. The external device can then begin sending data to the RM7000.

Figure 8 shows a processor block read request and the external agent read response for a system with either no tertiary cache or a transaction where the tertiary is being bypassed. The read latency is 4 cycles (**ValidOut*** to **ValidIn***), and the response data pattern is DDxxDD. Figure 9 shows a processor block write where the processor was programmed with write-back data rate boot code 2, or DDxxDDxx. Again, either there is no tertiary or it is being bypassed.

Finally, Figure 10 on page 14 shows a typical sequence resulting in two outstanding reads both with initial tertiary cache accesses. In this sequence;

1. the processor issues a read which misses in the tertiary,
2. the external agent takes control of the bus in preparation for returning data to the processor,

3. the processor encounters another internal cache miss and therefore asserts **PRqst*** in order to regain control of the bus,
4. the external agent pulses **PAck*** returning control of the bus to the processor,
5. the processor issues a read for the second miss
6. which also misses in the tertiary, and
7. the external agent retakes control of the bus and begins returning data (out of order) for the second miss to the processor.
8. The **RspSwap*** pin is asserted low to denote the out of order response. Not shown is the completion of the data transfer for the second miss or any of the data transfer for the first miss.

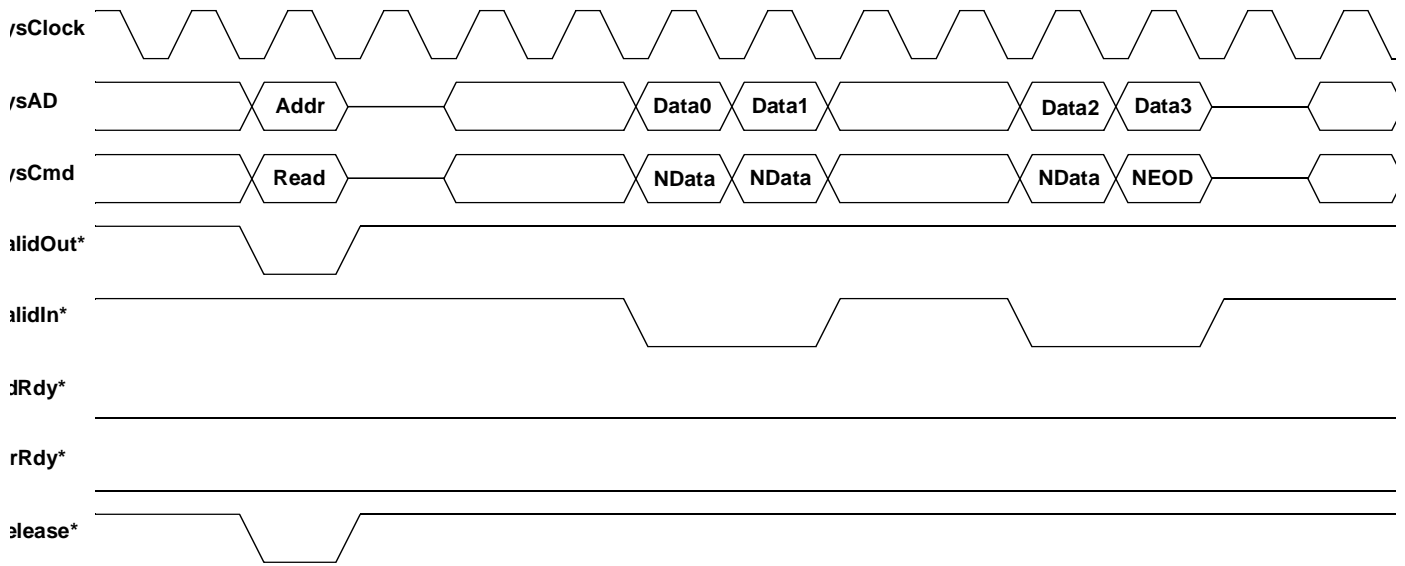

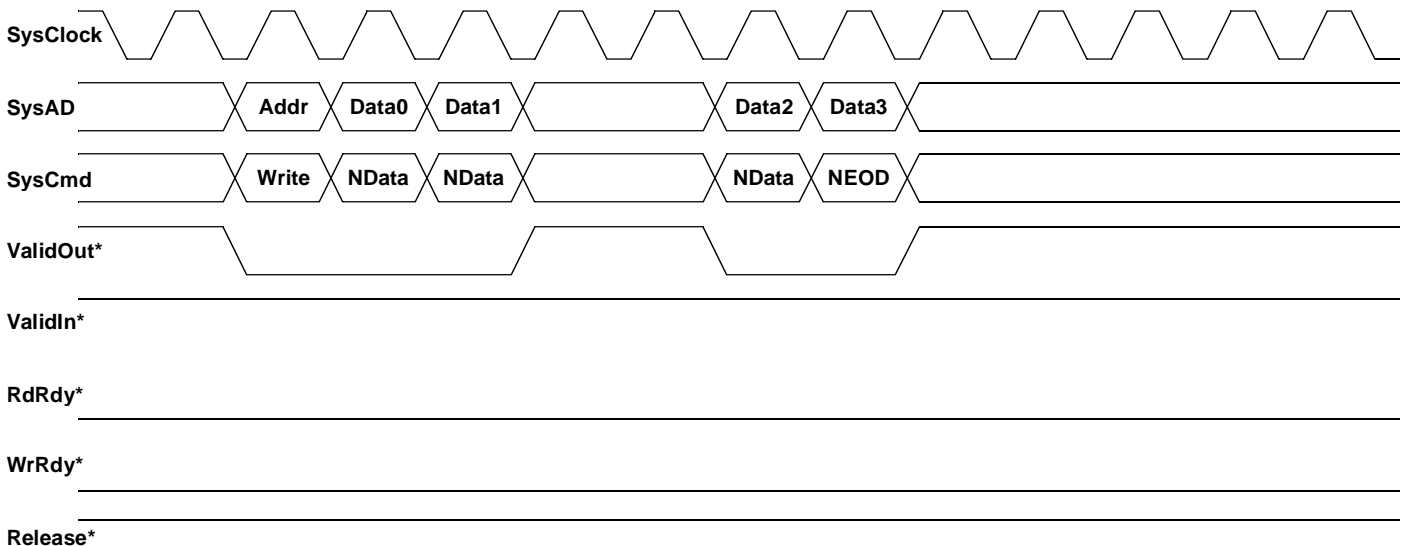

Figure 8 Processor Block Read

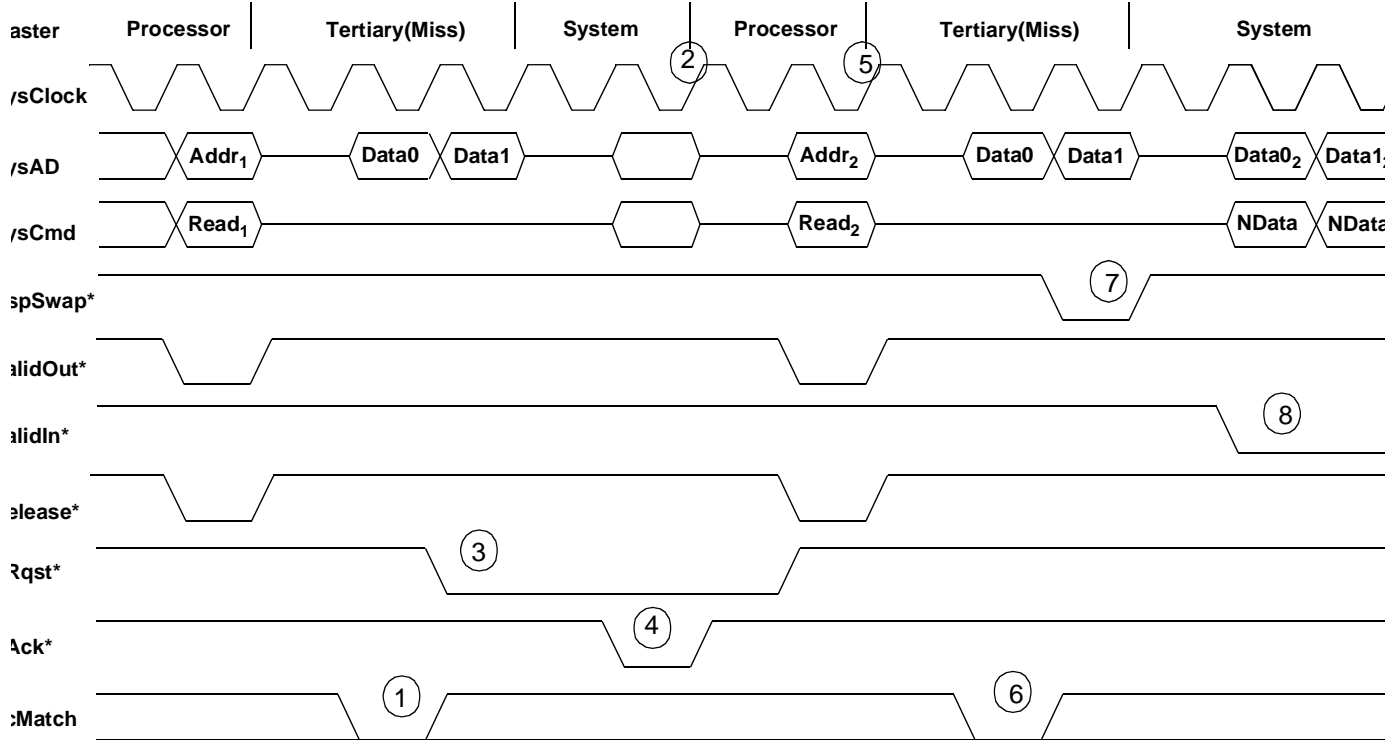

Figure 9 Processor Block Write

Figure 10 Multiple Outstanding Reads

Data Prefetch

The RM7000 is the first QED design to support the MIPS IV integer data prefetch (**PREF**) and floating-point data prefetch (**PREFX**) instructions. These instructions are used by the compiler or by an assembly language programmer when it is known or suspected that an upcoming data reference is going to miss in the cache. By appropriately placing a prefetch instruction, the memory latency can be hidden under the execution of other instructions by the processor. If the execution of a prefetch instruction would cause a memory management or address error exception the prefetch is turned into a nop; that is, no prefetch will occur and no exception will be taken.

Enhanced Write Modes

Like previous QED processor designs, the RM7000 implements two enhancements to the original R4000 write mechanism: Write Reissue and Pipeline Writes. In write reissue mode, a write rate of one write every two bus cycles can be achieved. A write issues if **WrRdy*** is asserted two cycles earlier and is still asserted during the issue cycle. If it is not still asserted then the last write will reissue. Pipelined writes have the same two bus cycle write repeat rate, but can issue one additional write following the deassertion of **WrRdy***.

External Requests

The RM7000 can respond to certain requests issued by an external device. These requests take one of two forms: *Write* requests and *Null* requests. An external device executes a write request when it wishes to update one of the processors writable resources such as the internal interrupt register. A null request is executed when the external device wishes the processor to reassert ownership of the processor external interface. Typically a null request will be executed after an external device, that has acquired control of the processor interface via ExtRqst*, has completed an independent transaction between itself and system memory in a system where memory is connected directly to the SysAD bus. Normally this transaction would be a DMA read or write from the I/O system.

Test/Breakpoint Registers

To increase both observability and controllability of the processor thereby easing hardware and software debugging, a pair of Test/Break-point, or Watch, registers, *Watch1* and *Watch2*, have been added to the RM7000. Each Watch register can be separately enabled to watch for a load address, a store address, or an instruction address. All address comparisons are done on physical addresses. An associated register, *Watch Mask*, has also been added so that either or both of the Watch registers can compare against an address range rather than a specific address. The range granularity is limited to a power of two.

When enabled, a match of either Watch register results in an exception. If the Watch is enabled for a load or store address then the exception is the Watch exception as defined for the R4000 with Cause exception code twenty-three. If the Watch is enabled for instruction addresses then a newly defined Instruction Watch exception is taken and the Cause code is sixteen. The Watch register which

caused the exception is indicated by Cause bits 25..24. Table 9 summarizes Watch operation.

Table 9:   Watch Control

Register	Bit Field/Function					
	63	62	61	60:36	35:2	1:0
Watch1, 2	Store	Load	Instr	0	Addr	0
	31:2				1	0
Watch Mask	Mask				Mask Watch 2	Mask Watch 1

Performance Counters

Like the Test/Break-point capability described above, the Performance Counter feature has been added to improve the observability and controllability of the processor thereby easing system debug and, especially in the case of the performance counters, easing system tuning.

The Performance Counter feature is implemented using two new CP0 registers, *PerfCount* and *PerfControl*. The *PerfCount* register is a 32-bit writable counter which causes an interrupt when bit 31 is set. The *PerfControl* register is a 32-bit register containing a five bit field which selects one of twenty-two event types as well as a handful of bits which control the overall counting function. Note that only one event type can be counted at a time and that counting can occur for user code, kernel code, or both. The event types and control bits are listed in Table 10.

The performance counter interrupt will only occur when interrupts are enabled in the *Status* register, IE=1, and **Interrupt Mask** bit 13 (**IM[13]**) of the coprocessor 0 interrupt control register is not set

Since the performance counter can be set up to count clock cycles, it can be used as either a) a second timer or b) a watchdog interrupt. A watchdog interrupt can be used as an aid in debugging system or software "hangs." Typically the software is setup to periodically update the count so that no interrupt will occur. When a hang occurs the interrupt ultimately triggers thereby breaking free from the hang-up.

Interrupt Handling

In order to provide better real time interrupt handling, the RM7000 provides an extended set of hardware interrupts each of which can be separately prioritized and separately vectored.

In addition to the six external interrupt pins available on the R4000 and R5000 family processors, the RM7000 provides four more interrupt pins for a total of ten external interrupts.

As described above, the performance counter is also a hardware interrupt source, Int[13]. Also, whereas the R4000 and R5000 family processors map the timer inter-

Table 10:   Performance Counter Control

9	Count in User Mode 0: Disable 1: Enable
10	Count Enable 0: Disable 1: Enable
31..11	Reserved (must be zero)

rupt onto Int[5], the RM7000 provides a separate interrupt, **Int[12]**, for this purpose freeing **Int[5]** for use as a pure external interrupt.

All of these interrupts, Int[9..0], the Performance Counter, and the Timer, have corresponding interrupt mask bits, IM[13..0], and interrupt pending bits, *IP[13..0]*, in the *Status*, *Interrupt Control*, and *Cause* registers. The *Interrupt Control* and *Cause* registers are illustrated below. The *Status* register has not changed from the RM52xx family and R5000, and is not shown.

The IV bit in the *Cause* register is the global enable bit for the enhanced interrupt features. If this bit is clear then interrupt operation is compatible with the RM52xx family and R5000. Although not related to the interrupt mechanism, note that the *W1* and *W2* bits indicate which Watch register caused a particular Watch exception.

In the *Interrupt Control* register, the interrupt vector spacing is controlled by the Spacing field as described below. The **Interrupt Mask** field (**IM[15..8])** contains the interrupt mask for interrupts eight through thirteen. **IM[15..14]** are reserved for future use. The **Timer Exclusive** (TE) bit if set moves the Timer interrupt to Int[12]. If clear, the Timer interrupt will be or'ed into Int[5] as on the R5000.

The *Interrupt Control* register uses **IM13** to enable the Performance Counter Control.

Priority of the interrupts is set via two new coprocessor 0 registers called *Interrupt Priority Level Lo, IPLLO*, and *Interrupt Priority Level Hi, IPLHI*. These two registers contain a four-bit field corresponding to each interrupt thereby allowing each interrupt to be programmed with a priority level from 0 to 13 inclusive. The priorities can be set in any manner including having all the priorities set exactly the same. Priority 0 is the highest level and priority 15 the lowest. The format of the priority level registers is illustrated below. The priority level registers are located in the coprocessor 0 control register space. For further details about the control space see the section describing coprocessor 0.

In addition to programmable priority levels, the RM7000 also permits the spacing between interrupt vectors to be programmed. For example, the minimum spacing between two adjacent vectors is 0x20 while the maximum is 0x200.

This programmability allows the user to either set up the vectors as jumps to the actual interrupt routines or, if interrupt latency is paramount, to include the entire interrupt routine at the vector. The table below illustrates the complete set of vector spacing selections along with the coding as required in the *Interrupt Control* register bits 3 through 0.

In general, the active interrupt priority combined with the spacing setting generates a vector offset which is then added to the interrupt base address of 0x200 to generate the interrupt exception offset. This offset is then added to the exception base to produce the final interrupt vector address.

Standby Mode

The RM7000 provides a means to reduce the amount of power consumed by the internal core when the CPU would not otherwise be performing any useful operations. This state is known as Standby Mode.

Executing the **WAIT** instruction enables interrupts and enters Standby Mode. When the **WAIT** instruction completes the W pipe stage, if the SysAD bus is currently idle, the internal processor clocks will stop thereby freezing the pipeline. The phase lock loop, or PLL, internal timer/counter, and the "wake up" input pins: **Int[9:0]***, **NMI***, **ExtReq***, **Reset***, and **ColdReset*** will continue to operate

Table 11: Cause Register

others	reserved

in their normal fashion. If the SysAD bus is not idle when the **WAIT** instruction completes the W pipe stage, then the **WAIT** is treated as a **NOP**. Once the processor is in Standby, any interrupt, including the internally generated timer interrupt, will cause the processor to exit Standby and resume operation where it left off. The **WAIT** instruction is typically inserted in the idle loop of the operating system or real time executive.

JTAG Interface

The RM7000 interface supports JTAG boundary scan in conformance with IEEE 1149.1. The JTAG interface is especially helpful for checking the integrity of the processor's pin connections.

Boot-Time Options

Fundamental operational modes for the processor are initialized by the boot-time mode control interface. The boot-time mode control interface is a serial interface operating at a very low frequency (**SysClock** divided by 256). The low frequency operation allows the initialization information to be kept in a low cost EPROM; alternatively the twenty or so bits could be generated by the system interface ASIC.

Immediately after the **VccOK** signal is asserted, the processor reads a serial bit stream of 256 bits to initialize all the fundamental operational modes. **ModeClock** runs continuously from the assertion of **VccOk**.

Boot-Time Modes

The boot-time serial mode stream is defined in Table 16. Bit 0 is the bit presented to the processor when **VccOk** is de-asserted; bit 255 is the last.

Table 16: Boot-Time Mode Stream

Mode bit	Description
0	reserved (must be zero)

PIN DESCRIPTION

The following is a list of control, data, clock, tertiary cache, interrupt, and miscellaneous pins of the RM7000.

Pin Name	Type	Description
System interface:		
ExtRqst*	Input	External request Signals that the system interface is submitting an external request.
Release*	Output	Release interface Signals that the processor is releasing the system interface to slave state
RdRdy*	Input	Read Ready Signals that an external agent can now accept a processor read.
WrRdy*	Input	Write Ready Signals that an external agent can now accept a processor write request.
ValidIn*	Input	Valid Input Signals that an external agent is now driving a valid address or data on the SysAD bus and a valid command or data identifier on the SysCmd bus.
ValidOut*	Output	Valid output Signals that the processor is now driving a valid address or data on the SysAD bus and a valid command or data identifier on the SysCmd bus.
PRqst*	Output	Processor Request When asserted this signal requests that control of the system interface be returned to the processor. This is enabled by Mode Bit 26.
PAck*	Input	Processor Acknowledge When asserted, in response to PRqst*, this signal indicates to the processor that it has been granted control of the system interface.
RspSwap*	Input	Response Swap RspSwap* is used by the external agent to signal the processor when it is about to return a memory reference out of order; i.e., of two outstanding memory references, the data for the second reference is being returned ahead of the data for the first reference. In order that the processor will have time to switch the address to the tertiary cache, this signal must be asserted a minimum of two cycles prior to the data itself being presented. Note that this signal works as a toggle; i.e., for each cycle that it is held asserted the order of return is reversed. By default, anytime the processor issues a second read it is assumed that the reads will be returned in order; i.e., no action is required if the reads are indeed returned in order. This is enabled by Mode Bit 26.
RdType	Output	Read Type During the address cycle of a read request, RdType indicates whether the read request is an instruction read or a data read.
SysAD(63:0)	Input/Output	System address/data bus A 64-bit address and data bus for communication between the processor and an external agent.
SysADC(7:0)	Input/Output	System address/data check bus An 8-bit bus containing parity check bits for the SysAD bus during data cycles.
SysCmd(8:0)	Input/Output	System command/data identifier bus A 9-bit bus for command and data identifier transmission between the processor and an external agent.
SysCmdP	Input/Output	Reserved for system command/data identifier bus parity For the RM7000, unused on input and zero on output.
Clock/control interface:		
SysClock	Input	System clock Master clock input used as the system interface reference clock. All output timings are relative to this input clock. Pipeline operation frequency is derived by multiplying this clock up by the factor selected during boot initialization
VccP	Input	Vcc for PLL Quiet VccInt for the internal phase locked loop (Voltage equals VccInt).
VssP	Input	Vss for PLL Quiet Vss for the internal phase locked loop.
Tertiary cache interface:		

Pin Name	Type	Description
TcCLR*	Output	Tertiary Cache Block Clear Requests that all valid bits be cleared in the Tag RAMs. Many RAM's may not support a block clear therefore the block clear capability is not required for the cache to operate.
TcCWE*(1:0)	Output	Tertiary Cache Write Enable Asserted to cause a write to the cache. Two identical signals are provided to balance the capacitive load relative to the remaining cache interface signals.
TcDCE*(1:0)	Output	Tertiary Cache Data RAM Chip Enable When asserted this signal causes the data RAM's to read out their contents. Two identical signals are provided to balance the capacitive load relative to the remaining cache interface signals
TcDOE*	Input	Tertiary Cache Data RAM Output enable When asserted this signal causes the data RAM's to drive data onto their I/O pins. This signal is monitored by the processor to determine when to drive the data RAM write enable in a tertiary cache miss refill sequence.
TcLine(17:0)	Output	Tertiary Cache Line Index
TcMatch	Input	Tertiary Cache Tag Match This signal is asserted by the cache Tag RAM's when a match occurs between the value on its data inputs and the contents of the addressed location in the RAM.
TcTCE*	Output	Tertiary Cache Tag RAM Chip Enable When asserted this signal will cause either a probe or a write of the Tag RAM's depending on the state of the Tag RAM's write enable signal. This signal is monitored by the external agent and indicates to it that a tertiary cache access is occurring.
TcTDE*	Output	Tertiary Cache Tag RAM Data Enable When asserted this signal causes the value on the data inputs of the Tag RAM to be latched into the RAM. If a refill of the RAM is necessary, this latched value will be written into the Tag RAM array. Latching the Tag allows a shared address/data bus to be used without incurring a penalty to re-present the Tag during the refill sequence.
TcTOE*	Output	When asserted this signal causes the Tag RAM's to drive data onto their I/O pins.
TcWord(1:0)	Input/Output	Tertiary Cache Double Word Index Driven by the processor on cache hits and by the external agent on cache miss refills.
TcValid	Input/Output	Tertiary Cache Valid This signal is driven by the processor as appropriate to make a cache line valid or invalid. On Tag read operations the Tag RAM will drive this signal to indicate the line state.
Interrupt interface		
Int*(9:0)	Input	Interrupt Ten general processor interrupts, bit-wise ORed with bits 9:0 of the interrupt register.
NMI*	Input	Non-maskable interrupt Non-maskable interrupt, ORed with bit 15 of the interrupt register (bit 6 in R5000 compatibility mode).
JTAG interface:		
JTDI	Input	JTAG data in JTAG serial data in.
JTCK	Input	JTAG clock input JTAG serial clock input.
JTDO	Output	JTAG data out JTAG serial data out.
JTMS	Input	JTAG command JTAG command signal, signals that the incoming serial data is command data.
Initialization interface:		
BigEndian	Input	Allows the system to change the processor addressing mode without rewriting the mode ROM.
VccOk	Input	Vcc is OK When asserted, this signal indicates to the RM7000 that the 2.5V power supply has been above 2.0V for more than 100 milliseconds and will remain stable. The assertion of VccOk initiates the reading of the boot-time mode control serial stream.

Pin Name	Type	Description
ColdReset*	Input	Cold reset This signal must be asserted for a power on reset or a cold reset. ColdReset must be de-asserted synchronously with SysClock.
Reset*	Input	Reset This signal must be asserted for any reset sequence. It may be asserted synchronously or asynchronously for a cold reset, or synchronously to initiate a warm reset. Reset must be de-asserted synchronously with SysClock.
ModeClock	Output	Boot mode clock Serial boot-mode data clock output at the system clock frequency divided by two hundred and fifty six.
ModeIn	Input	Boot mode data in Serial boot-mode data input.
Pin Name	Type	Description
System interface:		
ExtRqst*	Input	External request Signals that the system interface is submitting an external request.
Release*	Output	Release interface Signals that the processor is releasing the system interface to slave state

ABSOLUTE MAXIMUM RATINGS

Symbol	Rating	Limits	Unit
V_{TERM}	Terminal Voltage with respect to VSS	−0.5 to +3.6	V
T_{CASE}	Operating Temperature	0 to + 85	°C
T_{BIAS}	Case Temperature Under Bias	−55 to +125	°C
T_{STG}	Storage Temperature	−55 to +125	°C
I_{IN}	DC Input Current	20	mA
I_{OUT}	DC Output Current	50	mA

Notes: 1. Stresses greater than those listed under ABSOLUTE MAXIMUM RATINGS may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operational sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect reliability.
2. V_{IN} minimum = -2.0V for pulse width less than 15ns. V_{IN} should not exceed 3.6 Volts.
3. When V_{IN} < 0V or V_{IN} > VccIO
4. Not more than one output should be shorted at a time. Duration of the short should not exceed 30 seconds.

RECOMMENDED OPERATION TEMPERATURE AND SUPPLY VOLTAGE

Grade	Temperature	Vss	VccIO	VccInt
Commercial	0°C to +85°C (Case)	0	3.3 ± 5%V	2.5V ± 5%

DC ELECTRICAL CHARACTERISTICS — COMMERICAL TEMPERATURE RANGE

(VccIO = 3.3V $\pm$ 5%; Tcase = 0°C to +85°C)
